

SWISS ONCOLOGY & HEMATOLOGY CONGRESS

Introduction

Hyperleukocytosis (HL) is defined by an increase in leukocytes > 100×10⁹ /L. Symptomatic HL is often associated with increased morbidity and is considered a medical emergency. Our aim was to primarily assess the main causes of HL, particularly if there are non-hematological causes. Then, we attempted to evaluate the use of leukocytapheresis (LCAP) and outcomes of patients with HL.

Methods

We searched the hospital database for adult patients with HL between 2013-2023. Patients with at least one episode of HL and no written objection to the general consent were further evaluated. We collected data for age, sex, leukocyte count, underlying cause of HL, use of LCAP and early mortality (death within 1 month since HL). We assessed possible predictors for LCAP by means of logistic regression models. Calculated odds ratio (OR) were adjusted for sex, age and maximal leucocytes.

Results

- We retrospectively analyzed 878'967 adult patients and identified 375 (0.04%) with HL.
- 285 did not object to general consent and comprised the population evaluated.
- 276/285 (97%) patients had an underlying hematological disease (Figure 1)
 - Median age 66.8 years (range 18.4-93.6), 32% female
- 9 HL patients had a non-hematological underlying cause (Figure 1)
 - Median age 61.7 years (range 53-81), 22% female
 - Median leucocyte count was 103.3×109 /L (range 100-161)
- Leukocytapheresis
 - 33/285 (11.6%) patients underwent LCAP

 - No patient with a non-hematological cause underwent LCAP
 - 95%CI 1.04-17.3) for AML

Conclusions

- Even in a tertiary hospital the presence of HL is an unusual event.
- The causes, as expected, are mainly hematological
- Non-hematological causes however exist and should not be neglected, most were paraneoplastic.
- this method at our institution.

Are there non-hematological causes of hyperleukocytosis? Hyperleucocytosis cases in a tertiary university hospital over 10 years
